The traditional paradigm in crop domestication has been origin from a wild relative within one or more geographically-defined centers followed by expansion to the modern-day extent of cultivation. Absent from this paradigm are the effects of hybridization between a diffusing nascent crop species and closely-related, locally-adapted wild relatives outside the center of origin. New methods have recently been employed to detect genome-wide patterns of introgression in a number of species. In this review, we will: 1) briefly describe these methods and provide a summary of their application for detecting crop-wild introgression, 2) review evidence supporting the hypothesis that wild-to-crop introgression has conferred local adaptation, 3) consider how the prevalence of this introgression alters traditional concepts of domestication, and 4) describe future advances in both basic and applied genetics that can be made through the study of introgression in agroecosystems.

Introgression methods and their applications

The recent availability of genome-wide resequencing and reduced-representation genotyping (*e.g.*, GBS and RAD-Seq) data, combined with new analytical methods, has facilitated comprehensive study of introgression across a number of species (**Table 1**).

1. High-density marker data can be used with haplotype-based and other methods to assign specific genomic regions to a taxon of origin and to identify introgression across taxa [1, 2, 3, 4, 5, 6].

The methods introduced here do not include those marginally estimating introgression/migration rate as a component in the complete demographic history, such as Approximate Bayesian Computation (ABC) [7], diffusion approximations for demographic inference (dadi) [8], sorts of isolation with migration model [9], and the multiple sequentially Markovian coalescent (MSMC) [10]. The collection of methods described different layers of genetic variation: diversity and divergence, haplotype variation and phylogenetic relationships. We focus here on analytical prospects and limitations and introduce only a few representatives of each category.

First, genomic regions of introgression in admixed populations were expected to show a low level of divergence from source population. F_{st} and d_{XY} , as well as derivatives such as G_{min} [6] and RND_{min} [5], are representatives of such statistics. The former two are insensitive to rare migrants, and are therefore poorer at detecting recent introgression, while the latter two overcome these disadvantages.

$$G_{min} = \frac{d_{min}}{d_{XY}} \quad (1)$$

where d_{min} is the minimum sequence distance between haplotypes in species X and Y.

$$RND_{min} = \frac{d_{min}}{d_{out}} \quad (2)$$

where d_{out} equals $(d_{XO} + d_{YO})/2$, the average sequence distance between each species and the outgroup (O). In addition, RND_{min} is sensitive to variable mutation rate, which is indicated by branch length to the outgroup taxa.

These statistics were recently developed into several new statistics, such as $U_{A,B,C(w,x,y)}$, by adding the divergence between non-admixed populations (A) and source population (C) as a comparison to that between admixed populations (B) and source population (C) [11]. This statistic summarizes number of sites, where one particular allele at frequency y in source population has a frequency bigger than x in admixed population (B) and a frequency smaller than w in non-admixed population (C). Similarly, $Q95_{A,B,C(w,y)}$ just sets a hard cutoff as 95th percentile of allele frequencies in panel B [11]. These two statistics were also designed to facilitate incorporation of two source populations (see details in [11]).

Second, local ancestry reconvolution (also known as chromosome painting) can identify the genomic regions that come from different source populations [12]. Such methods usually take phased haplotypes as input, but MULTIMIX [13] can take both phased and unphased haplotypes as input, unveiling the genomic ancestry from multiple source populations.

Third, ABBA-BABA statistics (also known as D-statistics) and their derivatives are widely applied to the search for signs of introgression in genomic patterns of shared derived variants between populations or species. Based on D-statistics, \hat{f}_d [1] and five-taxon D statistics [4] were developed to localize genomic regions under introgression. The former took allele frequencies from each population/species, and the latter detected introgression from the localized phylogenetic pattern. Their strength in identifying specific regions enables one to explore the relationships between introgression and recombination rate/gene density/distribution of deleterious alleles and to better understand the genomic regions penetrable to foreign gene flow.

Fourth, structure-related approaches are based on the popular software STRUCTURE [14], which provides an estimate of the fraction of each individual's genome coming from each population. Many approaches in this respect have been developed. Two of these, fineSTRUCTURE [3] and GLOBETROTTER [15], were selected as representations. Different from STRUCTURE, fineSTRUCTURE not only identifies the number of populations, but also estimates the probability that genomic regions belong to one or the other populations. GLOBETROTTER is a development of fineSTRUCTURE that allows for tracing back to an unsampled source population and dating admixture events.

2. Application of these approaches across a number of plant and animal species suggests introgression can play an adaptive role. For example, introgression from ancient hominins (*e.g.*, Neanderthals and Denisovans) to humans has been detected at loci controlling skin pigmentation, defense against pathogens, and toleration of high altitude (reviewed in [16]), introgression has conferred Müllerian mimicry across butterfly species ([17]; introgression has spread insecticide resistance across mosquito species [18], and introgression across *Mimulus* (*i.e.*,

monkeyflower) species has resulted in adaptation to pollinator preference and contributed to speciation [19].

Table 1: List and brief description of recently developed methods and examples of empirical studies employing these methods.

Figure 1: Wing coloration patterns in *Heliconius* and evidence for introgression across species based on Patterson’s *D*-statistic; adapted from [17].

Crop adaptation through introgression

Over the last few years, several high-profile publications based on genome-wide data have documented introgression between crops and wild relatives outside putative domestication centers. A history of introgression during diffusion appears to be the rule for crops rather than the exception.

1. Theory suggests that colonizing species will overwhelmingly be recipients of introgression from locally-adapted native species [20]. Crops, given their frequent history of diffusion from defined centers of origin, are therefore potential recipients of adaptive introgression.
2. Recent empirical studies have revealed that introgression has occurred in many of the world’s most important crops (**Table 2**).

(a) Maize:

Maize (*Zea mays* ssp. *mays*) and the teosinte *Zea mays* ssp. *mexicana* (hereafter referred to as *mexicana*) have long been the subject of research into adaptive crop/wild introgression. Maize was domesticated from (*Zea mays* ssp. *parviglumis*) approximately 9,000 years ago in the Balsas River Valley [21]. From this domestication center, maize spread into the highlands of the Mexican central plateau, where it came into sympatry with wild *mexicana*. Introgression between *mexicana* and Mexican highland maize has been reported based on evidence from both morphological data [22, 23, 24] and molecular analyses [25, 26, 27, 28, 29]. However, [30] was the first to reveal evidence of adaptive introgression from *mexicana* into Mexican highland maize. The authors identified nine genomic regions which showed evidence of introgression from *mexicana* to maize in both the HAPMIX and the linkage model of STRUCTURE analyses with over seven sympatric population pairs among the nine pairs sampled. Among the nine regions, three span the centromeres of chromosomes 5, 6, and 10, and one is located in the inversion polymorphism on chromosome 4, suggesting a significant role of genome structures restricting recombination in adaptive introgression. By further characterizing the nine introgression regions, it is found that most regions contain long tracts of zero diversity, enriched with QTL linked with anthocyanin content and leaf macrohairs [23] and over-represented with the SNPs demonstrating high association with temperature seasonality. It was also revealed that in the growth chamber experiment, maize populations with introgression from *mexicana* on chromosomes 4 (associated with QTLs controlling pigment density and macrohairs) and 9 (overlapped with QTLs for macrohairs) exhibited more macrohairs and greater pigmentation under the highland environmental settings than the populations with absence of introgression from *mexicana*. In summation, the introgressed alleles/haplotypes from *mexicana* to maize conferred adaptation to highland habitats when maize migrated from Mexican lowlands.

Even though introgression from *mexicana* to Mexican highland maize has been highly supported, it is yet unknown whether and to what extent such introgression could be

found in other highland maize populations which are allopatric to *mexicana*. A recent study [31] found little empirical or theoretical support for parallel highland adaptation in the Mexican and South American highland regions, which was explained partly by the difference in potential for adaptive introgression from wild relatives. Adaptive SNPs in Mexican highland population were more likely located in the introgressed regions than those in South American highland populations. Furthermore, the adaptive SNPs in the Mexican highland population were more likely also showing signatures of local adaptation in *mexicana* and *pulviglium* populations than those South American highland population. For these reasons, adaptive introgression from wild relatives may play a significant role in patterning the genetic differences of maize highland populations.

Several questions regarding *mexicana* introgression yet remain. Has the introgression from *mexicana* spread to multiple highland populations? How do highland-adaptation traits differ among populations with and without introgression from *mexicana*? A recent study [?] first utilized the ABBA-BABA statistics to evaluate the existence or absence of introgression from *mexicana* to multiple highland populations, and then \hat{f}_d statistic proposed by Martin et al. (2015) [?] were calculated to locate the introgressed loci. Figure ?? shows the loess regression of \hat{f}_d in 10kb nonoverlapping windows across chromosomes 4 and 5 in multiple comparisons. On chromosome 4 (Figure ??), Mexican highland (MexHigh) and Guatemalan highland (GuaHigh) exhibited strong evidence of introgression from *mexicana*, and the peaks of distribution corresponded to the region identified in Hufford et al. (2013) [30]. The signal of introgression is absent for the other three populations. On chromosome 5, the signals of introgression (the peak region of the distribution) are present in MexHigh, GuaHigh and Southwestern US Highland (SW_US), but not the other two. More details on the other chromosomes can be found in [?]. Overall, both analyses revealed that gene flow from *mexicana* exists, not only to MexHigh maize, but also to GuaHigh maize, as well as to some individuals in SW_US, but not to the Andes and South American lowland (SA_Low) populations, suggesting different extent contributions *mexicana* made to multiple maize highland landrace populations. The Andean maize, the population totally isolated from the occurrence of any teosinte species, underwent the severest historical bottleneck, as a population in the front wave of the serial founder effects. The high frequency of deleterious alleles caused by stronger genetic drift in the Andes population, together with the reduced efficiency of selection against deleterious sites, contributes to the observed higher mutation load in the well-isolated maize population. Although it is clear that the absence of introgression from wild relatives provided fewer genetic resources for highland adaptation (making the highland adaptation in the Andes unique), it is yet unknown whether or not being out of reach of wild relatives is a reason for reduced fitness in the Andes population. Furthermore, the question of whether convergent evolution occurs between populations with and without introgression from wild relatives is a key topic for future studies in maize.

(b) Asian Rice:

Introgression appears to have played an important role in the domestication history of rice. The center of Asian rice (*Oryza sativa*) domestication is not known with complete confidence, but genetic and archaeobotanical evidence points towards both the Yangtze Basin in China and the Ganges plains in India for *O. sativa*, 8,200-13,500 years ago, from wild *O. rufipogon* [32, 33, 34, 35] or "the Asian form of *O. perennis* complex" [32]. Asian rice readily hybridize both with other domesticated subspecies and with wild relatives

(of which there are about twenty [34]). The high genetic diversity within *O. sativa* is likely due to introgression with wild relatives both during domestication and upon the dispersal of *O. sativa* into new environments and sympatry with new relatives [36].

In an attempt to categorize the varieties of Asian rice, [37] performed isozyme polymorphism analysis (11 enzymes, 20 loci, 79 alleles) on 25,519 rice varieties. The vast majority of the rice varieties fell into two groups; indica (73.45%) and japonicas (23.02%). Japonica rice cultivars were likely domesticated first from wild rice populations in southern China, and indica cultivars later developed through hybridization of ancient japonica with new wild rice populations in south and southeast Asia [38, 39]. However, about 1.26% belonged to four other groups (and 2.27% were indeterminate). Some of the varieties from these other four groups most likely arose from hybrids of cultivated rice and *O. rufipogon*. Introgression of alleles between cultivated rices, as well as between cultivated and wild rices, is common [32, 36, 40] and natural introgression from wild to domesticate is suspected ([40] calls for research into this possibility). These rices often have blight resistance gene, likely imparted from the wild relative parent. Several resistance genes (grassy stunt virus, bacterial blight, brown planthopper, blast) are known to have been introgressed from wild relatives into *O. sativa* by researchers [41, 42]. Some aus and rayada varieties retain characteristics of the putative wild parent. Aus exhibits a sprawling growth pattern and easy-threshing grain. Rayada is adapted to areas with longer periods of flooding, with heightened seed dormancy and photoperiod sensitivity (permitting harvest during times without standing water). Aswina variety, adapted to growth in deepwater conditions with a short period of flooding, seems to be the result of hybridization between *O. sativa* and deepwater-adapted *O. rufipogon* populations.

In addition to investigative experiments, gene flow from wild relatives has been utilized to produce agronomic rice varieties. Yatsen No. 1, for example, showed resistance to pests and diseases and adapted well to environmental conditions [43]. Several lines were derived from Yatsen No. 1, and went on to be utilized extensively in parts of China.

(c) Barley:

Domesticated and wild barleys belong to the same species, *Hordeum vulgare*, and are biologically capable of producing viable offspring via hybridization [44]. Barley (*Hordeum vulgare* subsp. *vulgare*) is believed to have been domesticated at least twice, once from wild subsp. *spontaneum* in the Fertile Crescent and once from subsp. *spontaneum* var. *agriocrithon* in Tibet roughly 10,000 years ago [32, 45, 46, 47, 48] but many of the details of barley domestication are still disputed.

Variety *agriocrithon* is genetically diverse, and is found throughout much of the range of barley. Some have suggested that *agriocrithon* may be the progenitor of six-rowed barley, the product of a hybridization between eastern and western cultivated barley, or a wild-domesticate hybrid [49, 50, 51] but [47] dispute these theories, suggesting instead that it arose from ssp. *spontaneum*, perhaps more than once (in Israel as well as in Tibet). Presently, the distribution of *spontaneum* consists of the Mediterranean, the Middle-East, and west-central Asia, while other barley wild relatives inhabit Asiatic regions (including Tibet) more broadly [52, 53, 54]. These wild relatives inhabit regions spanning such abiotic clines as temperature, precipitation, soil type, and altitude, as well as biotic clines [52].

There has been little genetic investigation into spontaneous barley/*spontaneum* hybrids [55]. Barley/*spontaneum* hybrids are fertile, and morphologically intermediate (putatively hybrid) barleys are found when wild and domesticated barleys are grown in sympatry,

but hybrids of other wild relatives generally exhibit greatly diminished fertility [53, 55] Even when the two are not grown immediately adjacent to one another, introgression from wild to domesticate has been shown to happen over distances of more than a kilometer [56].

The barley domestication process has reduced the number of alleles in the domesticate to only 40% of that found in wild barley, though there remains a great deal of phenotypic diversity among the wild barleys [57] Wild-domesticate breeding experiments have shown that wild barleys have alleles for several important agronomic phenotypes, including brittleness, flowering time, plant height, lodging, and yield [58, 59] The authors of [60] used STRUCTURE to look for patterns of introgression from wild relatives in a dataset of 803 landraces. The authors found a high amount variability in the amount of contribution from wild relatives, as well as its location in the genome, within barley populations. This is indicative of contribution from numerous wild populations. Furthermore, the authors find that wild introgression contribution is generally greatest from geographically-proximate populations, and that introgressed regions might be combined from geographically-separate wild populations. Low linkage disequilibrium and small blocks of identity by state indicate that these introgressed regions are old, perhaps dating back to the beginning of domestication. As landraces and nearby wild relatives share similar genomic sequences, the introgressed regions that are exclusive to that landrace are more more likely to contain adaptive alleles.

The barley domestication process has reduced the number of alleles in the domesticate to only 40% of that found in wild barley, though there remains a great deal of phenotypic diversity among the wild barleys [57] Wild-domesticate breeding experiments have shown that wild barleys have alleles for several important agronomic phenotypes, including brittleness, flowering time, plant height, lodging, and yield [58, 59].

(d) Sunflower:

The common sunflower (*Helianthus annuus*) shows evidence of domestication in eastern United States [61, 62] with additional evidence of a possible second origin of domestication in Mexico [63] Pre-Columbian *H. annuus* distribution spanned much of the Great Plains, from what is now north-central Texas up to and through Montana and North Dakota (see figure 1 of [64]). Domesticated sunflower has long lived in sympatry with wild relatives like *H. petiolaris* and *H. bolanderi* and forms stable hybrid populations [65, 66, 67] Many wild sunflowers are locally-adapted, and weedy hybrid populations share these adaptations [68]. However, the most striking example of adaptive introgression within *Helianthus* is that of the cucumberleaf sunflower, *H. debilis* ssp. *cucumerifolius*. Cucumberleaf sunflower is endemic to south-central Texas, and exhibits several adaptations to the region. Introgressive hybridization imparted locally-adapted alleles from *H. debilis* to *H. annuus* via introgressive hybridization. These introgressed hybrids formed a new lineage of sunflower (*H. annuus* ssp. *texanus*, *H. a. texanus* hereafter) which displays *H. debilis*-like traits adaptive to south-central Texas climate and ecology. These adaptive *debilis*-like traits include resistance to herbivorous pests and an increased branching plant architecture, as well as higher overall fitness than *H. annuus* (as measured by higher seed production)[69]. Although *H. annuus* and *H. a. texanus* are interfertile, *H. a. texanus* displays persistent phenotypic differences from *H. annuus*. The genome of the common sunflower has been greatly influenced by introgression from wild relatives, due to both natural outcrossing events and concerted breeding efforts in crop improvement. *Helianthus* has several genes for downy mildew resistance, and each

imparts resistance to one or more races of *Plasmopara halstedii*, one of the most agro-nomically important diseases in sunflower cultivation [70] Some of these downy mildew resistance genes were found in wild relatives (including *H. argophyllus*, *H. tuberosus*, and *H. praecox*) and have been successfully bred into modern *H. annuus* [71] P1Arg, an allele found in wild silverleaf sunflowers (*H. argophyllus*, inbred line Arg1575-2), confers resistance to all known (20 or more) races of downey mildew [72] while others (P11-P111) are effective for one or more types [73] Silverleaf sunflower has also been the focus of drought resistance breeding efforts [74] and *Phomopsis* resistance breeding efforts [75]. *H. annuus* shows signs of persistent introgressive hybridization with *H. petiolaris* with evidence of positive selection driving some of the genetic differentiation between the two species [76].

Recent investigations into the history of *Helianthus* introgression have implemented genomic methods. [77] analyzed transcriptome sequence variation on cultivated and wild *H. annuus*, *H. petiolaris*, and *H. argophyllus*. Using STRUCTURE, these authors found that introgressions from wild relatives can be found on every chromosome in at least one modern line, covering over 10% of the genome. Of particular note is the modern line RHA 274, a modern line which was bred with *H. a. texanus* in the 1970s to restore a branching plant body architecture, which allows the plant to produce pollen for a longer period of time, increasing seed production. RHA 274 has several large introgression from *H. a. texanus*, including one at the site of HaGNAT, the domestication gene associated with branching. These introgressed regions are not found in the non-branching lines Sunrise and VNIIMK8931, further suggesting that the *H. a. texanus* introgressed regions are causative.

3. Predictions regarding the likelihood of adaptive introgression in additional crops can be made through comparison of their centers of origin to both their current extent of cultivation and the distribution of wild relatives across environmental gradients (**Figure 2**).

Table 2: Overview of literature evaluating potential for crop-wild introgression in the world’s 15 most important crops including a column of references and a column summarizing major findings. **Figure 2:** Multi-panel figure showing maps of crop centers of domestication, distributions of wild relatives, and current extent of cultivation across gradient of precipitation. This figure will illustrate the adaptive potential of wild-to-crop introgression.

Re-evaluating concepts of domestication

A framework in which crops were domesticated from a single population or even a single species is, in several instances, an oversimplification. A demography incorporating introgression from additional sources appears to be more correct for many crops. With this in mind, certain aspects of crop evolution must be re-evaluated:

1. Estimates of the initial domestication bottleneck may be skewed when introgression is not considered. Chromosomal regions experiencing introgression may have an altered effective

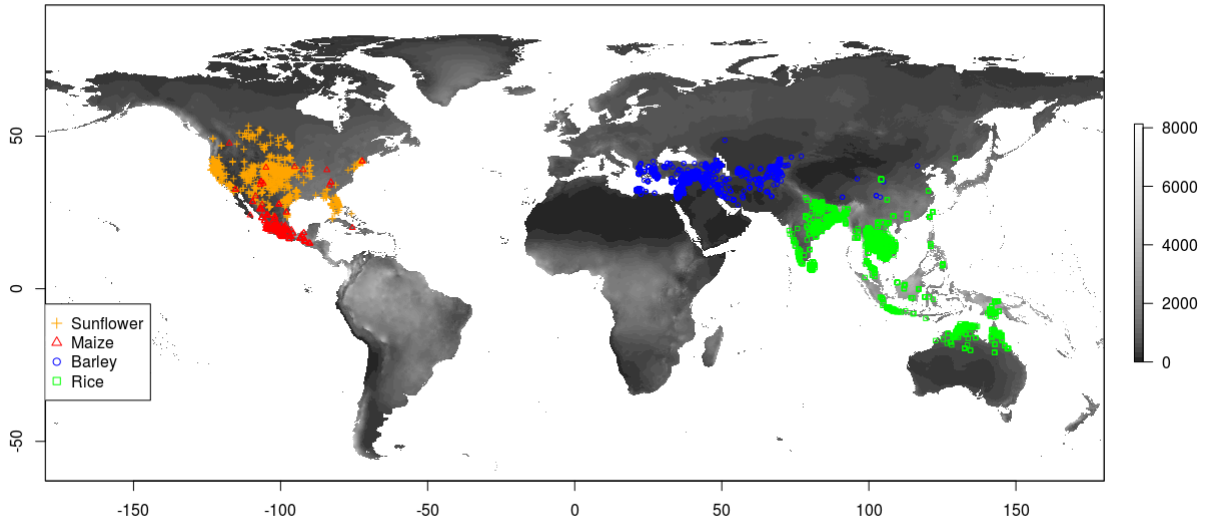

Figure 1: Map of the domestication centers of four crops and the distribution of their interfertile wild relatives, overlaying average annual precipitation.

population size (N_e) relative to non-introgressed regions depending on diversity within the donor taxon. For example, introgression from wild taxa with historically high N_e will lead to underestimates of the strength of the domestication bottleneck.

2. Estimates of the timing of domestication based on levels of sequence divergence may be affected when introgressed haplotypes are included.
3. Loci under selection during domestication are often identified based on signatures of substantially-reduced nucleotide diversity in the domesticated taxon relative to the wild progenitor and high allele frequency differentiation between these taxa. Introgression may alter these signatures and confound detection of domestication loci.

Future studies in crop-wild introgression

Additional study of introgression in agroecosystems could lead to advances in both basic and applied genetics:

1. Basic questions:
 - (a) To what extent does the level of introgression across taxa depend on divergence time between donor and recipient taxa?
 - (b) At what geographic scale does adaptive introgression occur? Is introgression frequently restricted to very local populations or is it often seen over broad geographic ranges? To what extent does this depend on the slope of environmental gradients such as temperature, precipitation, and elevation?
 - (c) Can colonizing species served as bridges for gene flow between previously allopatric taxa?
2. Applications:

Figure 2: The distribution of average annual precipitations experienced in the geographic home ranges of wild relatives interfertile with four crops

- (a) Loci underlying the domesticated phenotype which may be beneficial targets for crop improvement can be more clearly identified by removing the confounding population genetic signal of introgression.
- (b) Adaptive introgression that is clearly tied to a specific environment may include beneficial alleles that can be utilized in crop breeding.
